Abstract—Wireless sensor networks have been widely used for surveillance in harsh environments. In many such applications, the environmental data are continuously sensed, and data collection by a server is only performed occasionally. Hence, the sensor nodes have to temporarily store the data, and provide easy and on-hand access for the most updated data when the server approaches. Given the expensive server-to-sensor communications, the large amount of sensors and the limited storage space at each tiny sensor, continuous data collection becomes a challenging problem.

In this paper, we present *partial network coding* (PNC) as a generic tool for the above applications. PNC generalizes the existing *network coding* (NC) paradigm, an elegant solution for ubiquitous data distribution and collection. Yet, PNC enables efficient storage replacement for continuous data, which is a major deficiency of the conventional NC. We prove that the performance of PNC is quite close to NC, except for a sub-linear overhead on storage and communications. We then address a set of practical concerns toward PNC-based continuous data collection in sensor networks. Its feasibility and superiority are further demonstrated through simulation results.

I. INTRODUCTION

A wireless sensor network consists of a large collection of sensor nodes, which are often deployed in an open area with no traditional wired or wireless network support. Being a complement to conventional networks, a sensor network has its unique features and hence challenges. They are not only short of battery power, but also restrained by memory storage. As a result, one sensor can store only a small amount of data collected from its surroundings, and a large quantity of sensors have to work collaboratively for data gathering, storing, and replicating. To collect the data from sensors, an agent or base station (referred to as a *server* in this paper) functions as an intermediate gateway between a sensor network and the remote world.

Many recent studies are interested in data collection from harsh and extreme environments [6][26]. In these environments, the communications between sensors and the server can be expensive and scarce, and the data are collected occasionally. In each data collection, a fast data retrieval is usually desired [6]. Typical examples include the habitat monitoring system in Great Duck Island [20]; some birds are notoriously sensitive to human intervention, and thus,

data collection are done occasionally. In each collection, the presence of human being should be minimized and, hopefully, far away from the habitat center. Applications of monitoring systems in chemical plants also share similar properties, where technicians occasionally approach the sensing area to collect data and each data collection should be performed quickly for safety purposes.

In the current popular data collection techniques, the server sends out a query to a root sensor and the root sensor spread the query to the sensor network. The data are then routed from the source sensors to the root sensor. This collection technique, however, is not suitable for applications described above. First, this technique can introduce a long delay in each data collection due to data searching and aggregation [13][24]. Second, this technique is beneficial if data can be aggregated so that the payload will be reduced in the intermediate nodes. If raw data are required, then the root sensor will be burdened by uploading all data from the sensor network to the server. A random selection technique is thus suggested in [6]. In this scenario, data are redundantly stored in the sensor network and server randomly access a few sensor nodes to retrieve data. This server accessing (also known as *blind access*) is easy to implement. If the data can be retrieved accurately, the scheme is also much faster. In addition, it inherently distributes the communication cost from the root sensor to multiple sensor nodes, which balances the load.

Unfortunately, as illustrated in Fig. 1, this straight forward approach may introduce large replication.

Redundancy management have been studied in many known coding algorithms, e.g., different types of erasure codes [3]. Most of these codes, however, are generated at a central entity and then distributed to different storage locations. This is not realistic in our application, because no sensor is capable to store all the data, let alone to perform complicated encoding operations. A potential solution rises from *network coding* [6][26], which distributively manipulates the data in each node. Such operations combine all (say, N) data segments, making the coded data segments being equivalent to each other in decodeability. Thus, each sensor can store a small number of data segments and the server can decode all the original data as long as N combined data segments are collected. A fast

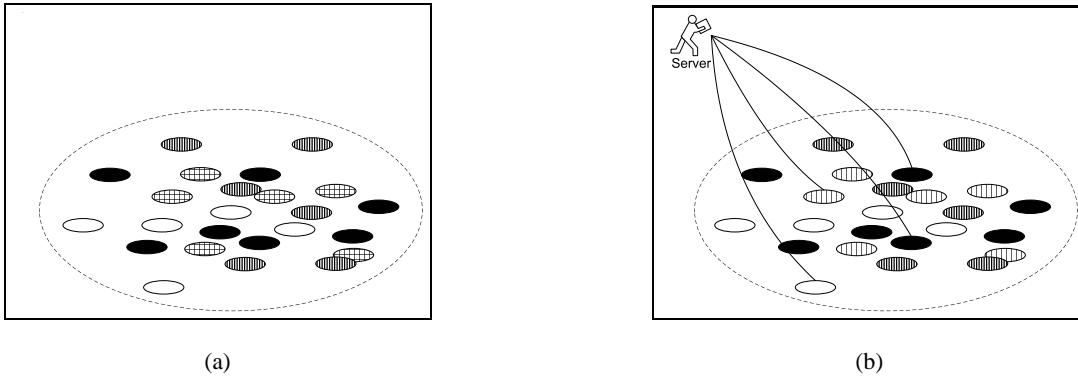

Fig. 1. An illustrative example of blind access. There are 4 different data segments distributed in the network. Each sensor (represented by a small circle) can store only one data segment (represented by the texture). (a) Server is absent. (b) Server access. The server randomly contacts several sensors to upload data. In this example, the server contacts 4 sensors, and unfortunately obtains only 3 different data segments.

and load-balanced data collection is then realized.

A key deficiency of the conventional network coding is the lack of support for removing obsolete data. In harsh environments, where the server may only approach occasionally, the sensor network has to temporarily store the data. The sensors may have to remove obsolete data segments to accommodate newly collected ones. To achieve this, conventional network coding has to first decode and then re-encode the combined data, which is time- and resource-consuming [10]. Even worse, given that a sensor can only store a partial set of the combined data, it is generally impossible to carry out decoding operations in each individual sensor.

In this paper, we present *Partial Network Coding* (PNC), which effectively solves the above problems. PNC inherits the blind access capability of NC, and yet achieves the following salient features: 1) It enables a higher degree of freedom in coded data management, in particular, decoding-free data removal; 2) Its computation overhead for encoding and decoding is almost identical to the conventional network coding; and 3) We proved that its performance is quite close to the conventional network coding as well, except for a sub-linear overhead on storage and communications. We also address a set of practical concerns toward building and maintaining a PNC-based sensor network for continuous data collection and replacement. The feasibility and superiority of PNC are further demonstrated through simulation results.

The remainder of this paper is organized as follows. In section II, we present the related work. We introduce the system model and motivations in section III. The theoretical foundations for PNC are established in section IV. In section V, we discuss the practical concerns toward using PNC in sensor networks. The performance of PNC is evaluated in section VI. Finally, we conclude the paper and discuss future directions in section VII.

II. RELATED WORK

Wireless sensor networks have been studied in various aspects and recent surveys can be found in [2][7]. In many applications, a sensor network is query based [19], where a server queries the sensors, and the latter cooperatively response

as a single entity. For such queries as Maximum, Minimum, Average, and Sum [24], a popular scheme is to construct a tree among the sensor nodes with the root being responsible for collecting data. This scheme works well if the data can be aggregated in the intermediate sensors [12][14]. In our application, we are interested in blindly collecting the up-to-date raw data from the sensor network, which calls for different solutions.

Coding is a powerful tool for randomized data storage and collection. A typical coding scheme is *erasure code* [3][16], where a centralized server gathers all N data segments and builds C coded segments, $C \geq N$. If any N out of C coded segments are collected, the original data segments can be decoded [8][18]. A practical investigation of these codes can be found in [22]. As mentioned before, these centralized operations are not suitable for our application environment that involves a large quantity of tiny sensors. An alternative is linear network coding [1][28], which distributes the encoding operations to multiple nodes. Network coding was first introduced to improve the throughput of a network [1], and was later suggested for efficient data storage and distribution [5]. Using network coding for data distribution is further theoretically studied in [21] (referred to as *random linear coding*), and a practical system for random file access is presented in [10]. Recently, network coding and its extensions have been introduced in wireless sensor networks for ubiquitous data collection [6][26]. In these studies, the data segments to be collected are static and fixed. We on the contrary focus on continuous data, where obsolete data have to be evicted from a limited buffer. The proposed partial network coding complements the previous studies by demonstrating a fully localized algorithm that enables the removal of obsolete data.

Our application scenario is also closely related to the extreme network architecture. A popular example is the ZebraNet in Africa [15], where researchers have to travel to the sensor network in person to collect data. Other recent examples can be found in [6][25][26]. One important feature of these networks is that the connection between the server and the sensor network is intermittent, and each node needs to store data temporarily and submits data when needed; but, again,

TABLE I
SUCCESS RATIO OF THE NAIVE SCHEME ($W = N, B = 1$)

N	Success Ratio	N	Success Ratio
2	0.5	6	0.0154321
3	0.222222	7	0.0061199
4	0.09375	8	0.00240326
5	0.0384	9	0.000936657

they generally assume that the data are never obsolete, which is different from our focus.

III. PRELIMINARIES

A. Model and Notations

We now give the formal description of the system. We assume that the total number of up-to-date events to be recorded in the whole system is N . Each event is represented by one data segment, denoted by c_j , and $c_{j'}$ is fresher than c_j if $j' > j$. Similar to existing studies on linear network coding, we use $\sum_{j=0}^{N-1} \beta_j \times c_j$ to generate a coded data segment f_i , where $\beta = (\beta_0, \beta_1, \dots, \beta_{N-1})$ is a co-efficient vector, each item of which is randomly generated from a finite field F_q . Since the coding can be viewed as a combination process, f_i is also referred to as a *combined* data segment, and c_j as an *original* data segment. Notice that after the combination process, the size of f_i remains equal to c_j . We define the *cardinality* of f_i to be the number of original data segments it contains, and the *full cardinality* of the system is the highest possible number, i.e., N .

The total number of sensors in the network is M , and each has a buffer of size $B (< N)$ for storing the data segments. For each server access, W sensors are to be contacted and, without loss of generality, each sensor will upload one data segment from its buffer.

Clearly, to obtain all the N original data segments, we must have $W \geq N$, and even so, not all the segments are necessarily obtained in one access. Consider a naive data storage and collection scheme without coding. Assume that all N up-to-date original segments are stored uniformly in each sensor's buffer. Then the success ratio for this naive scheme is given by $\prod_{i=0}^{N-1} \frac{N-i}{N}$. Here, the success ratio serves as the major evaluation criterion in our study, and is defined as follows:

Definition 1: (Success Ratio) The *success ratio* is the probability that a scheme successfully collects all the N original data segments. The default settings of W and B are $W = N$ and $B = 1$, which are their lower bounds for valid schemes.

For the naive scheme, its success ratio is a decreasing function of N . As shown in Table I, even for $N = 2$, the probability is barely 50%, and the performance is extremely poor for larger N .

B. Network Coding based Data Collection: Superiority and Problems

We now show that network coding can significantly increase the success ratio. With network coding, all data segments are stored in a combined fashion, and the N original data

Fig. 2. The coding base of PNC for $N = 4$. We omit the coefficient vectors.

segments can be decoded by solving a set of linear equations after collecting any N combined data segments. A necessary condition here is that the coefficient vectors must be linearly independent. This is generally true if the coefficient vector is randomly generated from a large enough field F_q [21]. As shown in Table II, the probability of linear independency is over 99.6% for $q = 2^8$, and this is almost independent of N . As such, for the network coding based data storage and collection scheme, the success ratio with $W = N$ and $B = 1$ is close to 100%.

In network coding, it is easy to combine new data segments to existing data segments, which increases the cardinality. The reverse operation is difficult, however. Specifically, to remove a data segment, we have to first decode the combined data segments, remove the obsolete data and re-encode the remaining ones to new data segments. This is time- and resource-consuming for power limited sensors. Even worse, it is often impossible for sensors where $B < N$, as decoding requires N combined data segments. On the other hand, for continuously arrived data, if we keep obsolete data segments in the system, the cardinality will only increase and eventually, the system crashes and no data can be decoded. This becomes a key deficiency for applying network coding in continuous data collection.

IV. PARTIAL NETWORK CODING BASED DATA STORAGE AND REPLACEMENT

In this section, we show a new coding scheme that conveniently solve the problem of data removal, thus facilitating continuous data management. Our coding scheme enables the combination of only part of the original data segments, and we refer to it as *Partial Network Coding (PNC)*, cf. *network coding (NC)* and no network coding at all (*Non-NC*).

A. Overview of Partial Network Coding

In PNC, instead of having full cardinality of each combined data segment, we have varied cardinalities from 1 to N .

$$\begin{aligned}
s_0 &: \{c_3, c_1\}, & s_1 &: \{c_1, c_0\} \\
s_2 &: \{c_3, c_0\}, & s_3 &: \{c_3, c_1\} \\
s_4 &: \{c_3, c_2\}, & s_5 &: \{c_2, c_0\}
\end{aligned}$$

(a) Non-NC

$$\begin{aligned}
s_0 &: \{f_0 = 5c_3 + 2c_2 + 3c_1 + 4c_0, & f_1 = 7c_3 + 2c_2 + 3c_1 + 4c_0\} \\
s_1 &: \{f_0 = 3c_3 + 2c_2 + 10c_1 + c_0, & f_1 = 10c_3 + 2c_2 + 5c_1 + c_0\} \\
s_2 &: \{f_0 = 2c_3 + 5c_2 + 2c_1 + 4c_0, & f_1 = c_3 + 15c_2 + 6c_1 + 3c_0\} \\
s_3 &: \{f_0 = c_3 + 18c_2 + 9c_1 + 4c_0, & f_1 = c_3 + 8c_2 + 9c_1 + 14c_0\} \\
s_4 &: \{f_0 = 5c_3 + 2c_2 + 3c_1 + 4c_0, & f_1 = 2c_3 + 6c_2 + 3c_1 + 4c_0\} \\
s_5 &: \{f_0 = 7c_3 + 7c_2 + 9c_1 + 5c_0, & f_1 = 8c_3 + 8c_2 + 8c_1 + 4c_0\}
\end{aligned}$$

(b) NC

$$\begin{aligned}
s_0 &: \{f_0 = [c_3, c_2, c_1, c_0], & f_1 = [c_3, c_2]\} \\
s_1 &: \{f_0 = [c_3, c_2, c_1], & f_1 = [c_3]\} \\
s_2 &: \{f_0 = [c_3, c_2, c_1], & f_1 = [c_3, c_2]\} \\
s_3 &: \{f_0 = [c_3, c_2], & f_1 = [c_3]\} \\
s_4 &: \{f_0 = [c_3, c_2, c_1, c_0], & f_1 = [c_3]\} \\
s_5 &: \{f_0 = [c_3, c_2, c_1], & f_1 = [c_3, c_2]\}
\end{aligned}$$

(c) PNC

Fig. 3. Data distribution in 6 sensors (s_0 through s_5) each with two storage units. (a) Non-NC, only original data segments are stored, (b) NC, combined data segments are stored where the cardinality of each segment is $N (=4)$, (c) PNC, data are stored in a combined fashion where the cardinality are arbitrary. We omit the coefficients for each combined data segment in PNC.

Formally, for original data segments c_0, c_1, \dots, c_{N-1} , we have a coding base $\mathcal{B} = \{f^k | f^k = \sum_{j=k}^{N-1} \beta_j \times c_j, k \in [0, \dots, N-1], \beta_j \in F_q\}$. We omit β_j in our paper and use $f^k = [c_{N-1}, c_{N-2}, \dots, c_k]$ for ease of exposition. Notice that if \hat{k} denote the cardinality of a combined data segment, then the cardinality of f^k can be calculated by $\hat{k} = N - k$. The coding base for $N = 4$ is illustrated in Fig. 2. We may further drop the superscript k if the cardinality of the combined data segment is clear in its context.

In our application scenario, each sensor stores only a subset of these combined data segments given buffer size $B < N$. The storage for each sensor is $\mathcal{S} = \{f_i^k | f_i^k \in \mathcal{B}, 0 \leq i \leq B-1\}$. We may use f_i provided that k is clear in the context to represent the i th combined data segment in this sensor. An illustrative example is shown in Fig. 3, which also includes the corresponding NC and Non-NC. From 3(c), we can see that, when a new c_4 is generated and c_0 becomes obsolete, sensors s_0 and s_4 can simply drop the longest combined data f_0 in their respective buffers. The buffers of s_0 and s_4 then become $\{f_0 = [c_4, c_3, c_2], f_1 = [c_4]\}$ and $\{f_0 = [c_4, c_3], f_1 = [c_4]\}$, respectively. This simple example demonstrates the salient feature of PNC, that is, removing the obsolete data without decoding.

B. Data Storage and Replacement in PNC

It is worth noting that the decoding capability of PNC closely depends on the available cardinalities of the collected data. Therefore, we need to avoid an abrupt cardinality loss when the system is to remove an obsolete data segment. As the server access is occasional and unpredictable, and the sensors

for each access are randomly selected, a uniform cardinality distribution for the combined data segments in the sensor network is desirable, i.e., for each collected data segment, the probability of encountering any cardinality should be $\frac{1}{N}$.¹

In the sensor point of view, however, it can not have data segments of all different cardinalities in its limited buffer. More importantly, it is impossible for the sensors to know exactly what other sensors store. As such, maintaining the uniformity of cardinalities in the entire system becomes a great challenge for PNC.

We solve this problem by a *Data Replacement* algorithm locally executed at each sensor (Fig. 4). It translates the uniformity maintenance problem to a uniform configuration for the initial distribution; the latter is much easier to achieve.

Algorithm Data Replacement(c_n)

```

 $c_n$ : new original data segment
for  $i = 1 \dots B$ 
  randomly generate  $\beta_n$  from  $F_q$ 
  if  $\text{cardinality}(f_i) < N$ ,
     $f_i = \beta_n c_n + f_i$ 
  else
     $f_i = \beta_n c_n$ 

```

Fig. 4. Data Replacement Algorithm.

Theorem 1: If the cardinality is uniformly distributed, then after executing the Data Replacement algorithm (Fig. 4), the distribution of the cardinality remains uniform.

Proof: If the distribution of the cardinality is uniform, then the probability that a combined data has cardinality \hat{k} is $\frac{1}{N}$ for all $\hat{k} = 1 \dots N$. After executing Data Replacement, the probability that a combined data segment has cardinality \hat{k} is equal to the probability that this segment previously has cardinality $\hat{k} - 1$, $\hat{k} = 1 \dots N - 1$, and the probability for a combined data segment has cardinality 1 is equal to the probability it previously has cardinality N . Hence, the probability is still $\frac{1}{N}$, and the distribution remains uniform. ■

The above theorem suggests that the uniformity is inherently maintained in data replacement, and the algorithm is fully distributed and localized. Therefore, before network deployment, we can uniformly assign the cardinalities to the sensors. Assume $B = 1$; after the deployment, the sensor assigned with cardinality \hat{k} can wait for $N - \hat{k}$ events and record and combine the \hat{k} following events only. The initial cardinality distribution of the combined data in the sensors is then uniform. The above configuration can be easily generalized to larger buffer sizes.

C. Performance Analysis of PNC and Enhancements

We now analyze the performance of PNC. We also present two effective enhancements to improve its performance.

Theorem 2: The success ratio of PNC based data collection is no worse than the naive collection (Non-NC).

Proof: The only possibility for Non-NC to collect all the N original data segments is to collect each of them exactly

¹This condition will be further explained in the next subsection.

once. On the contrary, for PNC, if we can collect N combined data segments with every cardinality presents, then we can decode all the original data segments. Since the probability of collecting a specific data segment and that of encountering a cardinality are both $\frac{1}{N}$, the expected success ratio of PNC is no worse than Non-NC. Note that, some combinations without all the cardinalities can be decodable as well; hence, PNC could achieve a higher success ratio. ■

It is also worth noting that, when the buffer size of a sensor increases, it can upload a data segment of higher cardinality when queried. The success ratio of PNC will thus be improved. On the contrary, for Non-NC, since each sensor can only randomly picks the data segment from its buffer for uploading, its performance remains unchanged.

We go on to compare PNC and NC. We know that, by ignoring the linear dependency of coefficients and data removal, NC achieves 100% success ratio when $W = N$ combined data segments are collected. An interesting question is thus whether PNC can achieve the same performance, or, if not, what is the overhead. To give some intuition, we see that in PNC, the chances for encountering c_{N-1} and c_0 are not identical: the most up-to-date data segment c_{N-1} is easier to collect because every combined data segment contains c_{N-1} ; on the contrary, the oldest data segment c_0 (but not obsolete) exists in the combined data segment with cardinality of N only. As such, the decoding ratio with PNC after blindly accessing a subset of sensors could be lower than that with NC.

To address the above problem, we make two enhancements to the original PNC scheme. First, we extend the full cardinality of the system from N to $N + \sqrt{N}$; that is, in addition to N required data segments, we store another \sqrt{N} obsolete data segments in the system. These obsolete data segments makes the originally oldest data segment relatively “younger” and therefore more likely to be collected (see an illustration in Fig. 5.); Second, we expand the buffer size of a sensor to $B = \sqrt{N} + 1$, which facilitates the first enhancement. With these two modifications, the following lemma shows that there is a scheme such that each sensor can upload a data segment with cardinality at least N when queried.

Lemma 3: By extending the full cardinality of the system to $N + \sqrt{N}$ and the buffer size to $\sqrt{N} + 1$, each sensor can have a combined data segment with cardinality at least N in its buffer.

Proof: Consider the following storage scheme for each sensor: A sensor picks a random number $k \in [-\sqrt{N}, 0]$ (negative indices denote obsolete data segments) and stores combined data segments $f_0 = [c_{N-1}, \dots, c_k]$, $f_1 = [c_{N-1}, \dots, c_{k+\sqrt{N}}]$, $f_2 = [c_{N-1}, \dots, c_{k+2\sqrt{N}}]$, \dots , $f_{\sqrt{N}} = [c_{N-1}, \dots, c_{N-\sqrt{N}-k}]$. The difference of the cardinality between f_i and f_{i+1} is \sqrt{N} for all $0 \leq i \leq (B - 1)$. The buffer requirement of this scheme is $\sqrt{N} + 1$, and for any k the sensor chooses, the cardinality of f_0 is greater than N . In addition, after executing the Data Replacement algorithm, the cardinality of f_0 remains greater than N until it is discarded upon the arrivals of \sqrt{N} new data segments. After that, the cardinality of f_1 will be greater than N , and the iteration

Fig. 5. On the left hand side, the inner grey triangle denotes the original PNC with no extension. After extension, PNC-ext becomes the outer white triangle, with cardinality $N + \sqrt{N}$. Given buffer size $\sqrt{N} + 1$ for each sensor, one data segment is picked in every \sqrt{N} interval as shown by the lines.

$$\begin{aligned} f_0 &= [c_{N-1}, \dots, c_{N-\sqrt{N}-1}, \dots, c_{2\sqrt{N}-1}, \dots, c_0, \dots, c_{-\sqrt{N}}] \\ f_1 &= [c_{N-1}, \dots, c_{N-\sqrt{N}-1}, \dots, c_{2\sqrt{N}-1}, \dots, c_0] \\ f_2 &= [c_{N-1}, \dots, c_{N-\sqrt{N}-1}, \dots, c_{2\sqrt{N}-1}] \\ &\dots \\ f_{\sqrt{N}} &= [c_{N-1}, \dots, c_{N-\sqrt{N}-1}] \end{aligned}$$

Fig. 6. A snapshot of the buffer at a sensor. We can see that f_0 has a cardinality of $N + \sqrt{N}$ (with \sqrt{N} obsolete data segments combined). When a new c_N is generated, according to Data Replacement algorithm, it will be combined to all f_i , and f_0 will be discarded. f_1 however will have a cardinality of $N + 1$ (combined with one obsolete data segment c_0). We can guarantee that, at any given time, each sensor will have a data segment of cardinality at least N .

continues. ■

A concrete example is shown in Fig. 6, where we denote the \sqrt{N} obsolete data with negative indices. We then have the following observation on the performance of PNC as compared to NC.

Theorem 4: The success ratio of PNC with $B = \sqrt{N} + 1$ and $W = N + \sqrt{N}$ is 100% (neglecting linear dependency of the coefficients).

Proof: From Lemma 3, the server can collect $\sqrt{N} + N$ combined data segments with cardinality at least N . For decoding, we are trying to solve a set of linear equations, of which the coefficients form a $(N + \sqrt{N}) \times (N + \sqrt{N})$ matrix. Since the cardinality of each coefficient vector is at least N , then the rank of this matrix is at least N . Therefore, we can solve the first N variables (which contributes to the rank). ■

Corollary 5: The success ratio of PNC with $B = \sqrt{N} + 1$ and $W = N + \sqrt{N}$ is identical to the success ratio of NC with $B = 1$ and $W = N$.

In other words, after sacrificing a sublinear buffer overhead (\sqrt{N}) at each sensor and a sub-linear communication overhead (\sqrt{N}), the PNC is guaranteed to decode all the N original data segments in a blind access as NC does.

V. PROTOCOL DESIGN AND PRACTICAL ISSUES

In this section, we address some major practical concerns, and present a collaborative and distributed protocol for continuous data collection with PNC.

A. Computation and Communication Overheads

As the sensors are small and power constrained entities, the PNC operations must be light-weighted. It is known that the computational overhead for network coding lies mainly in the decoding process. This is however, performed in the powerful servers. Each sensor just needs to randomly generate a set of coefficients, combine newly arrived data with those in the buffer, or drop an obsolete combined data segment. All of these operations are relatively simple with low costs. Another overhead is the transmission cost. For network coding based application, besides the combined data, the coefficient vectors have to be uploaded for decoding. Such overheads are generally much lower than the data volume, and our simulation results have shown that the benefits of PNC dominate these overheads.

B. Multiple Data Pattern

In many applications, the sensor network is required to collect multiple data ranges or patterns. For example, the sensor network may need to track the temperature of multiple critical levels. Therefore, the sensors need to be invoked at different times to record different data sets. The problem here is whether to use a mixed storage with each sensor splitting its buffer to store different temperature levels, or just assign different subset of sensors to record different levels. The tradeoff is obvious: the former might record certain temperature levels incompletely if the buffer is too small, i.e., smaller than N ; the latter, while fully recording certain levels of temperature, will risk the incapability of decoding an entire level.

The above *all or nothing* effect is also considered in [4]. Yet, for PNC based collection, we can see that a larger buffer might provide data with higher cardinalities, and it is easy to add an importance parameter in our system. That is, for important data patterns, we can use more sensors to maintain them, and thus have higher probability to successfully collect them. We will further investigate the impact of the importance parameter in the next section through simulations.

C. Collaborative and Distributed Implementation

To guarantee success, our PNC suffers only a sublinear overhead (\sqrt{N}) in buffer storage and communication cost. In practice, if N is too big, even a buffer of size $\sqrt{N}+1$ might not be available at a tiny sensor. In addition, the buffer sizes of the sensors might not be identical. To overcome these problems, the sensors can work collaboratively to provide combined data segments when queried. Specifically, they can form clusters in advance, where the members of a cluster maintain different cardinalities. A cluster can then upload one highest cardinality data segment upon accessing.

We thus suggest the following collaborative and distributed implementation. We assume that the server is interested in m data patterns and, for each pattern, N_i recent data segments, $1 \leq i \leq m$. After deployment, each sensor will send a probe message to its surrounding area to form a cluster, where the number of sensors in this cluster, n , is greater than $\sum_{i=1}^m N_i$.

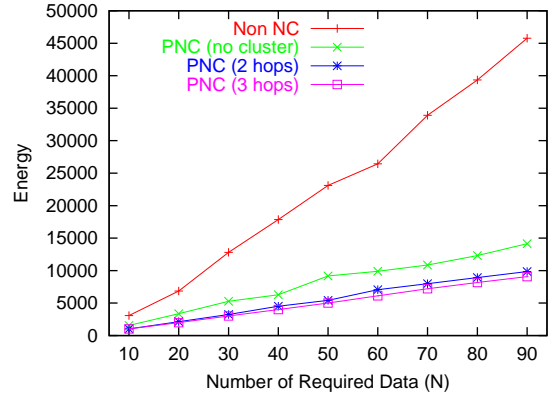

Fig. 7. Energy consumption as a function of N for different cluster radiuses.

Presumably, the sensors in one cluster can reside in 1 or 2 hops from each other. If n is too large, a two tier structure can be built, where each cluster in the first tier stores the data for a single pattern. A cluster head is then selected for each cluster, which distributes a storage schedule to the sensors in its cluster. When a sensor receives a server query, it first forwards this message to the cluster head; the cluster head checks whether this query is to search a data pattern associated with its own cluster. If so, the head will notify the sensor that currently has the combined data segment of the highest cardinality to upload the data; otherwise, it will forward the query to an appropriate head that is associated with the pattern for further processing.

VI. PERFORMANCE EVALUATION

A. Simulation Settings

In this section, we present our simulation results for PNC-based sensor data collection. We deploy 1000 sensors randomly into a field of $10\text{m} \times 10\text{m}$. The distance between the server and the sensor nodes is much larger than the distance between the sensors, and, as suggested in [17], we assume that there is a 10-fold difference. The server can thus access the data without necessarily entering deep into the sensor field, which is useful for data collection from a dangerous area. The default number of data segments that the server collects is the most recent 50 data segments ($N = 50$) and the default buffer size B is 1. We examine other possible values in our simulation as well. The linear equations in network coding are solved using the Gaussian Elimination [9], and the coefficient field is $q = 2^8$, which can be efficiently implemented in a 8-bit or more advanced microprocessor [26]. To mitigate randomness, each data point in a figure is an average of 1000 independent experiments.

B. Comparison of Energy Consumption

Since NC does not have the capability of data removal, it will eventually lead to a crash of the system in continuous data collection. Therefore, in our simulations, we only study the performance of PNC and compare PNC with Non-NC.

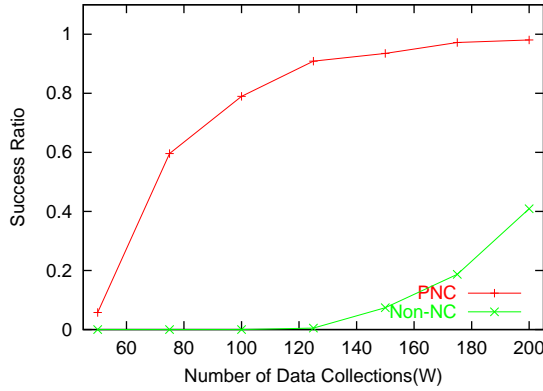

Fig. 8. Success ratio as a function of W for PNC and Non-NC.

We first compare the energy consumption of PNC with Non-NC. We use an energy consumption model of $E = d^4$ [27], where d is the transmission range. The field will generate events which are of interest in an hourly basis and the sensors will record these events. Server will randomly and occasionally approach with an expected interval of 20 hours. The server is interested in the most recent $N = 50$ data pieces. It will first randomly collect 50 data segments and if some original data segments are missing (for Non-NC) or the combined data segments can not be decoded (for PNC), then the server will send additional requests one by one, until all 50 data segments are obtained. The results are shown in Fig. 7.

It is clear that PNC performs better than Non-NC for different N . It can be seen that the energy consumptions are linear with respect to the number of required data (N), but the slope for PNC is much smaller. As a result, when N is greater than 50, the energy consumption with Non-NC is 3 to 4 times higher than that with PNC. The energy consumption with PNC is further reduced when clusters are employed (the cluster radius is set to 2 or 3 hops, respectively), because data segments with higher cardinalities could be uploaded from a larger aggregated buffer.

C. Performance of PNC

In our applications, when server approaches, a fast data collection is always desired. Therefore, it is better for the server to estimate the number of sensors it should query and send the query simultaneously, instead of in an incrementally fashion as previous section. Success ratio is thus a good indicator of how many sensors should be queried at once. Therefore, we use success ratio to evaluate the performance of PNC starting from this section.

1) *PNC vs Non-NC*: We revisit the performance of PNC and Non-NC using success ratio. Fig. 8 shows the success ratio as a function of the number of data segments collected (W). Not surprisingly, the success ratio increases when W increases for both PNC and Non-NC, but the improvement PNC is more substantial. For example, if 100 data segments are collected, the success ratio is about 80% for PNC; for

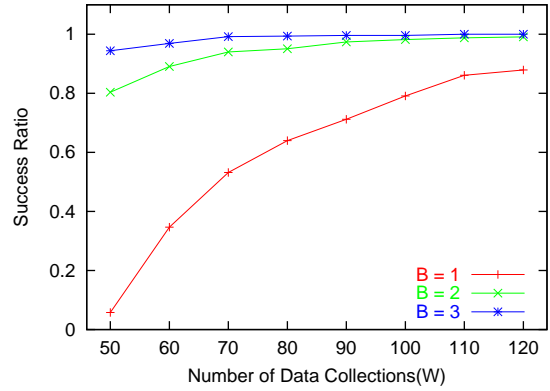

Fig. 9. Success ratio as a function of W with different buffer size.

Non-NC, after collecting 200 data segments, the success ratio is still 40% only.

2) *Effect of Buffer Size*: We then increase the buffer size from $B = 1$ to 2 and 3 to investigate its impact. We require the sensors to upload the data segment of the highest cardinality for each server access. The results are shown in Fig. 9, where a buffer increase from 1 to 2 has a notice improvement in success ratio, and a buffer of 3 segments delivers almost optimal performance. This is not surprising because there is a higher degree of freedom for storing and uploading data in a larger buffer space.

In our analysis, we show that given $W = N + \sqrt{N}$, and $B = \sqrt{N} + 1$ the system guaranteed to decode N original data segments (ignoring linear dependency). In this case, the server has to decode $N + \sqrt{N}$ data segments, among which \sqrt{N} are obsolete. An interesting question is thus: *Can we reduce the overhead for W but still guarantee an optimal success ratio?* Unfortunately, from Fig. 10, we can see that this unlikely happens. Among the 1000 experiments, only in 4 experiments the server successfully decodes before collecting all the $N + \sqrt{N}$ data segments. We conjecture that \sqrt{N} could be a lower bound of the overhead, though it has yet to be proved.

The above two sets of results suggest that PNC works quite well for a reasonable buffer size even without extension to include obsolete data segments. Therefore, unless a guarantee is desired, the straightforward PNC is enough for most applications.

3) *Impact of N* : We then explore the impact of the cardinality N . In Fig. 11, we depict the decoding ratio for different number of original data segments ($N=20, 50, \text{ and } 100$). The x -axis denotes the ratio between the number of data collected and the cardinality, i.e. $\lambda = \frac{W}{N}$. We can see from Fig. 11 that their differences are insignificant, and general reduce when W increases. Recall that, the performance of Non-NC decreases sharply when N increases, as shown in Table I, while NC is marginally affected by N only. These simulation results thus reaffirm that PNC inherits the good scalability of NC.

Fig. 10. Number of communication needed (W) to successfully decode N original data segments. $N = 50$ and $N + \sqrt{N} = 57$.

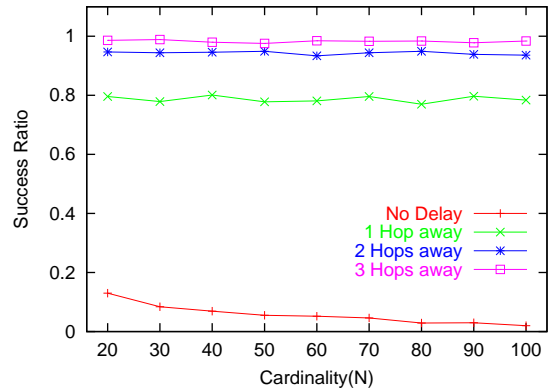

Fig. 12. Success ratio as a function of cardinality for different cluster radiuses.

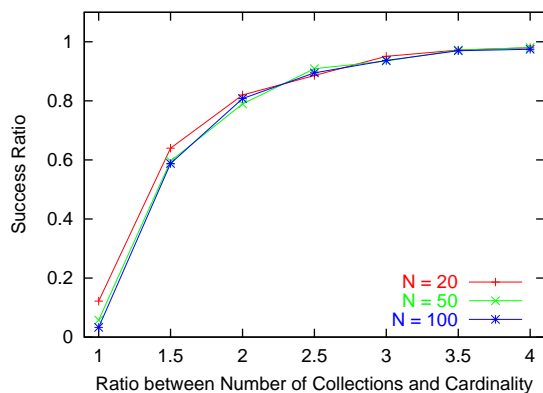

Fig. 11. Success ratio as a function of $\lambda = \frac{W}{N}$.

Fig. 13. Success ratio as a function of W for multiple patterns.

D. Effect of Clustering

As discussed in section V, to surpass the limited buffer size, the sensors can form clusters to achieve a larger aggregated buffer space. In Fig. 12, we show the success ratios for a buffer limited sensor network with different cluster radiuses, i.e., the number of hops to reach the farthest sensors, ranging from 0 to 3. When the radius is 0, there is basically no cluster and a contacted sensor has to respond to the server immediately using data from its local buffer. We can see that the success ratio significantly increase when the clustering algorithm is enabled. For a cluster radius of 2, it is already quite close to 100%.

E. Impact of Multiple Pattern

We next investigate the impact of requiring the sensor network to maintain multiple data patterns, e.g., to record more than one event of interest. Fig. 13 shows the success ratio for a 4-pattern scenario. To differentiate the importance of the patterns, we have assigned different number of sensors to each pattern (in this example, 12.5%, 12.5%, 25%, and 50% of the total number of sensors).

Not surprisingly, the success ratio favors data pattern with more sensors assigned. An interesting observation is that the

improvement is not uniform for all the four patterns, either. It favors first for the data pattern with the largest number of assigned sensors (50%), then the pattern with the second largest number of assigned sensors (25%), and so forth. This is clearly desirable given that we want to differentiate the patterns.

VII. CONCLUSIONS AND FUTURE WORK

In this paper, we introduced a novel coding scheme, Partial Network Coding (PNC), which effectively solves the problem of removing obsolete information in coded data segments. The problem is a major deficiency of the conventional network coding. We proved that the success ratio of PNC in data collection is generally better than a non-coding scheme and is close to the conventional network coding, except for a sub-linear overhead on storage and communication. We then addressed several practical concerns toward implementing PNC in resource-constrained sensors, and demonstrated a collaborative and fully distributed protocol for continuous data collection in large sensor networks.

In network coding research, it is known that the higher the cardinality is, the more the benefits we could expect. Therefore, many existing schemes have focused on achieving a full cardinality in data combination; For example, the

proposals in [5][6][10][21] generally increase the cardinality by combining as much data as possible in intermediate nodes and then forward to others. Our work on partial network coding, however, shows that the opposite direction is worth consideration as well.

Nevertheless, there are still many unsolved issues for PNC. Beyond the practical issues toward implementing a real PNC-based sensor network, we are interested in the following two questions: First, based on our simulations, we observe that the performance of PNC is very close to NC. We therefore suspect whether the overhead of \sqrt{N} reaches the potential limit of PNC? Second, our PNC is currently used for data collection only. We expect that an enhancement could facilitate more complicated queries. Given its flexibility in data management, we believe that PNC can be applied in many other applications, and the solutions to the practical and theoretical issues in PNC is thus urged, especially considering the recent flourish of data streaming in numerous fields.

ACKNOWLEDGMENT
